

Convective Clouds over the Bay of Bengal

PAQUITA ZUIDEMA

NOAA Environmental Technology Laboratory, Boulder, Colorado

ABSTRACT

The behavior of convective activity over the Bay of Bengal during the 1988 and 1999 monsoon seasons is examined using 3-hourly satellite infrared data. More organized convective activity, spreading farther south into the Bay, occurred in the 1988 than in 1999. A distinct spatial grouping of convective systems by size is found. The east side of the Bay experiences most of the rainfall over water, and here the convective systems are relatively small, short-lived, and frequent. At the northwest side of the Bay near most of the land-based rainfall, convective activity is organized into much larger and longer-lived systems. The diurnal cycle of all the systems over the Bay, regardless of size, shows a 6 A.M. local time maximum in very cold cloud tops (infrared brightness temperature < 210 K), with genesis occurring between 9 P.M. and 3 A.M. (9 P.M. for the larger, longer-lived systems). The cloud systems dissipate after sunrise, with the larger systems lasting until the afternoon. The land-water interface is important for the convection genesis and thereby affects the spatial distribution of convection. Offshore nocturnal convection begins near shore, with later convection occurring farther out over the Bay and attaining a larger size. The preference for nocturnal initiation times differs markedly from the afternoon initiation times typical of the tropical western Pacific ocean, but the time of maximum cloud area extent and dissipation are similar. The strength of the diurnal cycle varies greatly with location, with the northwest side of the Bay experiencing both the highest amount of very cold cloudiness and the strongest diurnal cycle. The Joint Air-Sea Monsoon Interaction Experiment (JASMINE) research cruise experienced the only multi-day sequence of large, diurnally-repeating, southward-moving disturbances at 89°E 11°N in the two years examined, but both the convective diurnal cycle and propagation direction were consistent with climatology. An interesting aspect of the convective lifecycle is that systems often have a southward component to their motion, with the most common propagation direction over the entire Bay being to the southwest. This can occur even when the larger scale movement is towards the northwest (such as is typical for cyclones at the northern end of the Bay).

1. Introduction

The Bay of Bengal in northern summer is the site of the highest mean precipitation of the entire Asian monsoon region and perhaps of the global oceans. The copious rainfall alone is consequential for human endeavors, and the accompanying latent heating helps drive the Asian monsoonal circulation. Despite the importance of the Bay of Bengal to both weather and climate, the region is poorly sampled and researched (Webster 2002). The dynamics and convection of the Bay of Bengal (and of

the entire Asian monsoon) is poorly simulated in models (e.g. Spencer and Palmer 1996), and the poor sampling further hampers efforts at model validation and improvement.

The call for research activity in the Bay of Bengal motivated its choice for both the Joint Air-Sea Monsoon Interaction Experiment (JASMINE; Webster 2002; Webster et al. 2002), carried out in May-June 1999 and the Bay of Bengal Monsoon Experiment (Bhat et al. 2001), held July-August 1999. JASMINE set out to document the intraseasonal variability of the Asian monsoon (with the onset of the monsoon being understood as the first intraseasonal oscillation of the monsoon season). Both quiescent and disturbed conditions were sampled.

FIG. 1. Mean rainfall in mm/hour for May-September 1999 using the TRMM 3B43 parameter, a merging of TRMM Precipitation Radar and Microwave Imager data with infrared data from geosynchronous satellites and rain gauge data over land. See Adler et al. (2000) for more explanation.

During the second intensive observing period occurring from May 21-26 (“Star 2”) large ($> 40,000 \text{ km}^2$), long-lived (1-2 day), nocturnal disturbances propagated due southward over the R/V *Ron Brown* (89°E , 11°N). Two of these disturbances are represented in Fig. 3b and Fig. 3d (more explanation on the figure is provided in Section 2). Large southward-propagating disturbances at this location have received little if any previous documentation.

This paper is in part an attempt to place the activity observed during JASMINE within a larger context. We seek to answer the following questions: How ubiquitous are large southward propagating storms in the Bay of Bengal? Are they a regular feature of monsoonal weather? Was their observed diurnal variability typical? A comprehensive satellite survey of convective activity within the Bay of Bengal is not yet available with which to answer these questions. What is known, however, points to a complicated climatology that is neither archetypically oceanic nor continental. Results from other regions, such as the western Pacific warm pool, will not necessarily apply to the Bay of Bengal.

Many independent datasets document a high degree of convective activity within the Bay of Bengal. Dataset examples include highly reflective cloud (Grossman and Garcia 1990), satellite microwave (Spencer 1993), outgoing longwave radiation (Roca and Ramanathan 2000),

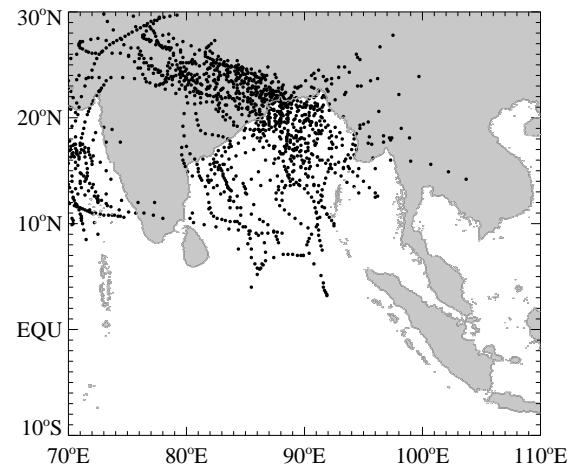

FIG. 2. All 6-hourly reports of cyclones between May and September of 1971-2000, as reported by the Joint Typhoon Warning Center at Guam.

TRMM¹ Precipitation Radar storm heights (Short and Nakamura 2000), and satellite lightning detection² (Toracinta and Zipser 2001). Perhaps the best direct rainfall measure is provided by the TRMM satellite Microwave Imager and Precipitation Radar data, merged with geosynchronous satellite infrared data and land-based rain gauge data (Adler et al. 2000). The estimated mean rainfall rate for May-September 1999 using this dataset is shown in Fig. 1 for the Bay of Bengal. The mean rainfall rate was the highest over the Bay of Bengal of anywhere over the globe for this time period.

Figure 1 shows that the rainfall was mostly concentrated in the east-northeast side of the Bay. Most of the rainfall takes place over water but favors being close to land. This locational preference is also seen in a 1979-1991 satellite microwave rainfall climatology (Spencer 1993) and in a spatial distribution of infrared-inferred cold cloud tops (Roca and Ramanathan 2000, Fig. 2). TRMM-identified precipitation features with ice scattering are also more numerous on the east side of the Bay than the west (Steve Nesbitt, personal communication; see Nesbitt and Zipser 2000, for more explanation).

While most of the rainfall occurs on the east side of the Bay, the more organized, larger-scale convective systems occur on the west-northwest side of the Bay. Fig-

¹Tropical Rainfall Measuring Mission

²The Bay of Bengal is one of the few large salt-body regions with a disposition for lightning, and lightning was routinely observed at night throughout JASMINE. Lightning tends to indicate strong vertical updrafts within convective cores.

ure 2 shows all six-hourly reports of cyclones for the same spatial domain as Fig. 1 for May through September of 1971–2000, as given by the Joint Typhoon Warning Center in Guam. A clear preference exists for the north-northwest side of the Bay. Monsoon lows, depressions, and disturbances are much more numerous (and possess weaker circulations) than cyclones, but have similar spatial distributions. Cyclones generally begin over water then move northwestward over land, often with severe impacts on human welfare.

A preference for the west side of the Bay is seen in other indicators of severe weather or high vertical motion, e.g., satellite-detected lightning frequency (Toracinta and Zipser 2001, Fig. 3), high (12–15 km) TRMM 30-dBZ echo heights (Steve Nesbitt, pers. comm.), high tropopause heights (Newell and Gould-Stewart 1981), and mesoscale convective complexes (MCCs) (Laing and Fritsch 1993). Lastly, the NCEP³ Reanalysis (Kalnay et al. 1996) places most precipitation at the northwest side of the Bay. The Reanalysis product is not a robust indicator of precipitation, but it does indicate favorable conditions for vertical ascent on a large spatial scale.

To date, the convection occurring within the Bay of Bengal remains incompletely documented. Many satellite studies of this region have relied on polar-orbiting satellites that pass over the region once a day at a set time, and have focused on larger-timescale phenomena such as intraseasonal oscillations (e.g., Lawrence and Webster 2001, and references therein). In part, the lack of a survey reflects a paucity of geostationary satellite data for this region. The Japanese Geostationary Meteorological Satellite and the European Meteosat satellites at their normal location have low viewing angles into the Bay of Bengal, which undermines their data quality. The geostationary Indian INSAT satellite is at an appropriate location, but its data are not available to western researchers on a continuous basis. One year of 3-hourly INSAT data is available through the NCAR⁴ Data Archive. These data have been applied in a few studies of the more extreme convective events in the Bay of Bengal, such as MCCs (Laing and Fritsch 1993) or tropical storms and cyclones (Smith and Mehta 1990). A more comprehensive analysis of convective activity is done by Roca and Ramanathan (2000), but this often averages over a large spatial domain that ignores unique conditions within the Bay of Bengal. The TRMM satellite is invaluable as a direct precipitation measure from space, but samples a particular location infrequently.

The focus of this study is to provide a comprehen-

sive survey, using 3-hourly geostationary infrared satellite imagery with viewing angles not too far from nadir, of the convective activity for this climatically important area, from the small, individual cloud to the large cloud complexes. In addition, their life cycle evolution is tracked from genesis, to maximum area attained, to end. The survey spans 1999 (the year JASMINE occurred) and 1988 for more completeness. The diurnal cycle is elucidated, partly to help identify the respective influences of land and water. Such studies have been done previously for other regions of the globe (e.g., Chen and Houze 1997; Chen et al. 1996; Machado et al. 1998; Mapes and Houze 1993; Mathon and Laurent 2001) but not for the Bay of Bengal domain.

Two geostationary infrared satellite datasets are used. One dataset comes from the Meteosat-5 satellite, which was moved to 63°E on April 19, 1999, in support of the JASMINE and INDOEX experiments. The second dataset is the 3-hourly INSAT Infrared Imagery of May–September 1988 mentioned previously. A pixel-grouping algorithm is used to identify a cloud cluster, which can then be tracked from image to image to characterize the temporal progression of convective events.

2. Data and Method

a. Data

The 3-hourly Meteosat-5 Infrared (10.5–12.5 μm) Imagery data of May–September 1999 were used. These were missing 5% of the total possible number of images, mostly in September. The missing images were randomly distributed throughout the diurnal cycle. The data showed no obvious signs of calibration change or other data dropout aside from the missing complete images. The infrared mean count at a 0.25° resolution were converted to brightness temperatures using coefficients provided with the data by the European organization for the exploitation of METeorological SATellites (EUMETSAT).

The second dataset is the 3-hourly INSAT Infrared Imagery of May–September 1988. The INSAT satellite is nominally located at 75°E. A count-to-brightness temperature conversion table was provided with the data. At the T_b thresholds used, the resolution is 1 K (Smith and Mehta 1990). The full-disk images have a spatial resolution of 22 km; these were interpolated to the same 0.25° resolution of Meteosat-5. Larger data gaps existed in the INSAT dataset than in the Meteosat-5 dataset, both in missing images (7.3% of possible total) and what appeared to be bit dropouts affecting some scan lines. Images were visually inspected, and those containing a large amount of data dropout within the Bay of Bengal

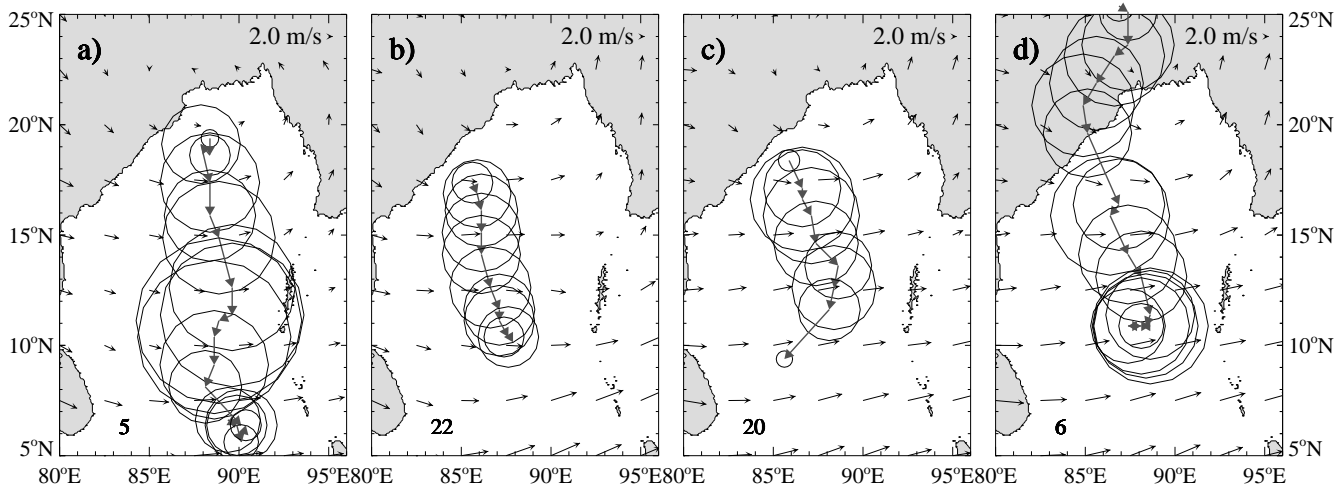

FIG. 3. Four examples of time clusters, as defined in Section 2, from May 1999. Panel a) took place from 0300 UTC 19 May - 0300 UTC 21 May, b) 2400 UTC 21 May - 0300 UTC 23 May, c) 0300 UTC 23 May - 0300 UTC 24 May, d) 0600 UTC 23 May - 0600 UTC 25 May. Each circle represents a closed contour of satellite-inferred $T_b < 218$ K, and corresponds roughly to the cloud cluster size. Arrows show the direction of the centroid from image to image. Superimposed is the daily- or two-day-average 850-mb NCEP Reanalysis wind field closest to the date(s) of the time cluster. The numbers in the bottom left-hand corner refer to the ranking of the event within the entire May-September season for the Bay of Bengal, i.e., the event in panel d) was the sixth largest in total area coverage of all events occurring within the Bay of Bengal between May 1 and September 30. The average propagation speeds for a)-d) are 8.5 m/s, 8.2 m/s, 11.6 m/s, and 9.3 m/s, respectively.

region were discarded from the analysis; this reduced the dataset a further 3%. The missing images were randomly distributed throughout time of day. The larger INSAT data dropout will cause an underestimation of the 1988 cold cloudiness, but cannot affect the result that 1988 contained more and larger coherent convective activity than 1999 (Section 3). The reported INSAT image times were not consistent, but were almost always within one half-hour of and rounded off to that 3-hourly time interval. No calibration issues are reported in the literature for either satellite instrument. The two satellite datasets are treated identically, and the focus is almost entirely on the Bay of Bengal, which is defined here to span from 5°N-25°N and 80°E-100°E.

b. Infrared Brightness Temperature Threshold

The infrared satellite literature contains a range of temperature thresholds, summarized in Mapes and Houze (1993) and Machado et al. (1998). Inferences made about convective activity and life cycles vary with the choice of temperature threshold (e.g., Mapes and Houze 1993; Mathon and Laurent 2001). One of these is that colder cloud tops correspond more closely to heavier rainfall events (Chen and Houze 1997; Rickenbach and Rutledge 1998). For this reason, we show results for two infrared temperature (T_b) thresholds: 235 K, to document the behavior of all clouds thought to be rain-

bearing, and 210 K, to document the behavior of the most heavily precipitating clouds.

The 235 K threshold was chosen because of a documented fit between area- and time-averaged rainfall and T_b (Arkin 1979; Ohsawa et al. 2001). The 235 K threshold is the commonly used Goes Precipitation Index (Arkin 1979), arrived at through correlating radar-based rainfall estimates and the satellite fractional area coverage of $T_b < 235$ K pixels on a 1.5° by 1.5° to 2.5° by 2.5° spatial scale during the GARP Atlantic Tropical Experiment. This threshold was tested again against rainfall gauge over India in Arkin et al. (1989), and found to perform well for most regions with the exception of the Ghat Mountains and the Gangetic Plain. A similar linear regression analysis of rainfall gauge data and satellite data by Ohsawa et al. (2001) over tropical Asia arrived at a T_b threshold choice of 230 K.

The 210 K threshold is taken as an indicator of the precipitation boundary within deep convective clouds. It is close to the 208 K threshold found to correspond best with the instantaneous precipitation area in radar-sampled deep convective systems over the western Pacific (Mapes and Houze 1993), and is used by Chen and Houze (1997) to examine diurnal variations in the life cycles of tropical deep convective systems.

The correspondence between the brightness temperature thresholds and precipitation is a core assumption for this study, but it is a statistical and not a literal relation-

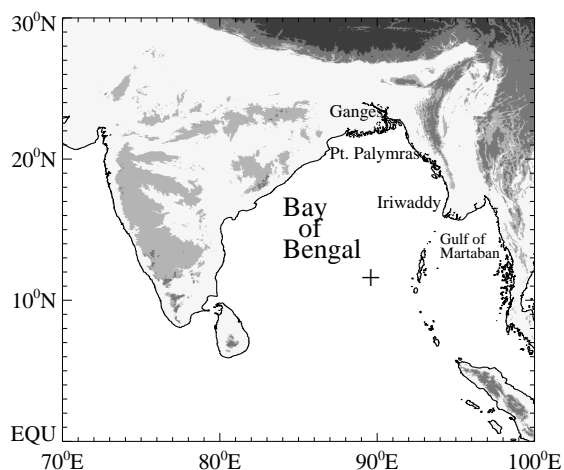

FIG. 4. Geography of the Bay of Bengal. Altitudes of 500, 1000, and 4000 meters are shown in progressively darker shades of gray. The '+' symbol indicates the position of the R/V *Ron Brown* during JASMINE IOP 2.

ship. Precipitation can originate from clouds with tops warmer than the threshold (R.-S. Sheu and Liu 1997; Short and Nakamura 2000). Alternately, clouds with very cold tops may simply be advected cirrus, especially for this region of high wind shear (see Rickenbach 1999, for more discussion).

c. Cloud Clustering and Tracking

The 235 K threshold is an unreliable indicator of precipitation on an individual pixel basis. Partly for this reason, cloud clusters were identified and tracked only through the 210 K threshold. Few clear cases of cirrus advected westward by the upper-level winds were seen with the 210 K threshold⁵. A colder threshold also provides better definition of a time cluster, with less subtleties in storm identity and continuation as cloud clusters merge and split up.

The method is simple:

1. "Cloud clusters" are closed countours of < 210 K T_b within each image (ie., all pixels must share at least one row or column with a neighboring cold pixel). Their area and the location of the centroid are determined. The data resolution means that the smallest cloud cluster, comprising one pixel only, will have an area of about 600 km^2 .

⁵The dissipating cluster in Fig. 3c may be an example of advected cirrus, but this example used a threshold T_b of 218 K.

2. "Time clusters" are cloud clusters within sequential images with overlapping positions. Their overlap must exceed either $10,000 \text{ km}^2$ or 50% of either cluster. The times, centroid locations, and area of the start and end of each time cluster are determined as well as when each time cluster achieves its maximum size. In addition, the total area covered by each time cluster during its lifetime is calculated. Cloud cluster merges and splits are taken into account throughout the time matching.

This procedure was previously developed and applied to characterize the Australian monsoon (Williams and Houze 1987), the area covered by the Japanese GMS satellite (Mapes and Houze 1993), and the tropical western Pacific warm pool (Chen et al. 1996). The method depends on slow cloud propagations between two sequential images relative to its size. For 3-hour resolution data, the areal overlap method performs well for clouds with areas of roughly $> 8,000 \text{ km}^2$ (Machado et al. 1998). This implies that we are only able to track cloud clusters of size larger than about 12 pixels from image to image. The simple but objective area overlap tracking approach is as functional as more elaborate methods that include cloud morphology and radiative criteria (Machado et al. 1998).

The time cluster lifetime and total area cloud coverage are dependent on the threshold chosen, with warmer thresholds corresponding to larger cloud areas, longer lifetimes, and slower propagation speeds (e.g., Mathon and Laurent 2001). The lifetimes and cloud areas deduced here using the 210 K threshold will be underestimates of the true convective area and lifetime. In addition, only literal, continuous propagations of convective activity will be identified, and larger-scale displacements of convective activity occurring within a larger envelope will be missed.

Examples of cloud clusters and time clusters, derived using a 218 K threshold, are shown in Fig. 3. A disturbance that passed over the RV *Ron Brown* during JASMINE is shown in Fig. 3b. The area covered by each circle is roughly to scale.

d. Geography

A map of the Bay of Bengal domain is shown here in Fig. 4. Pt. Palmyras refers to the convex peninsula on the Indian coast, the Iriwaddy refers to the convex coastline formed by the broad delta of the Iriwaddy river, with the Gulf of Martaban to its southeast. The plus sign indicates the position of the R/V *Ron Brown* during the second intensive observing period of JASMINE.

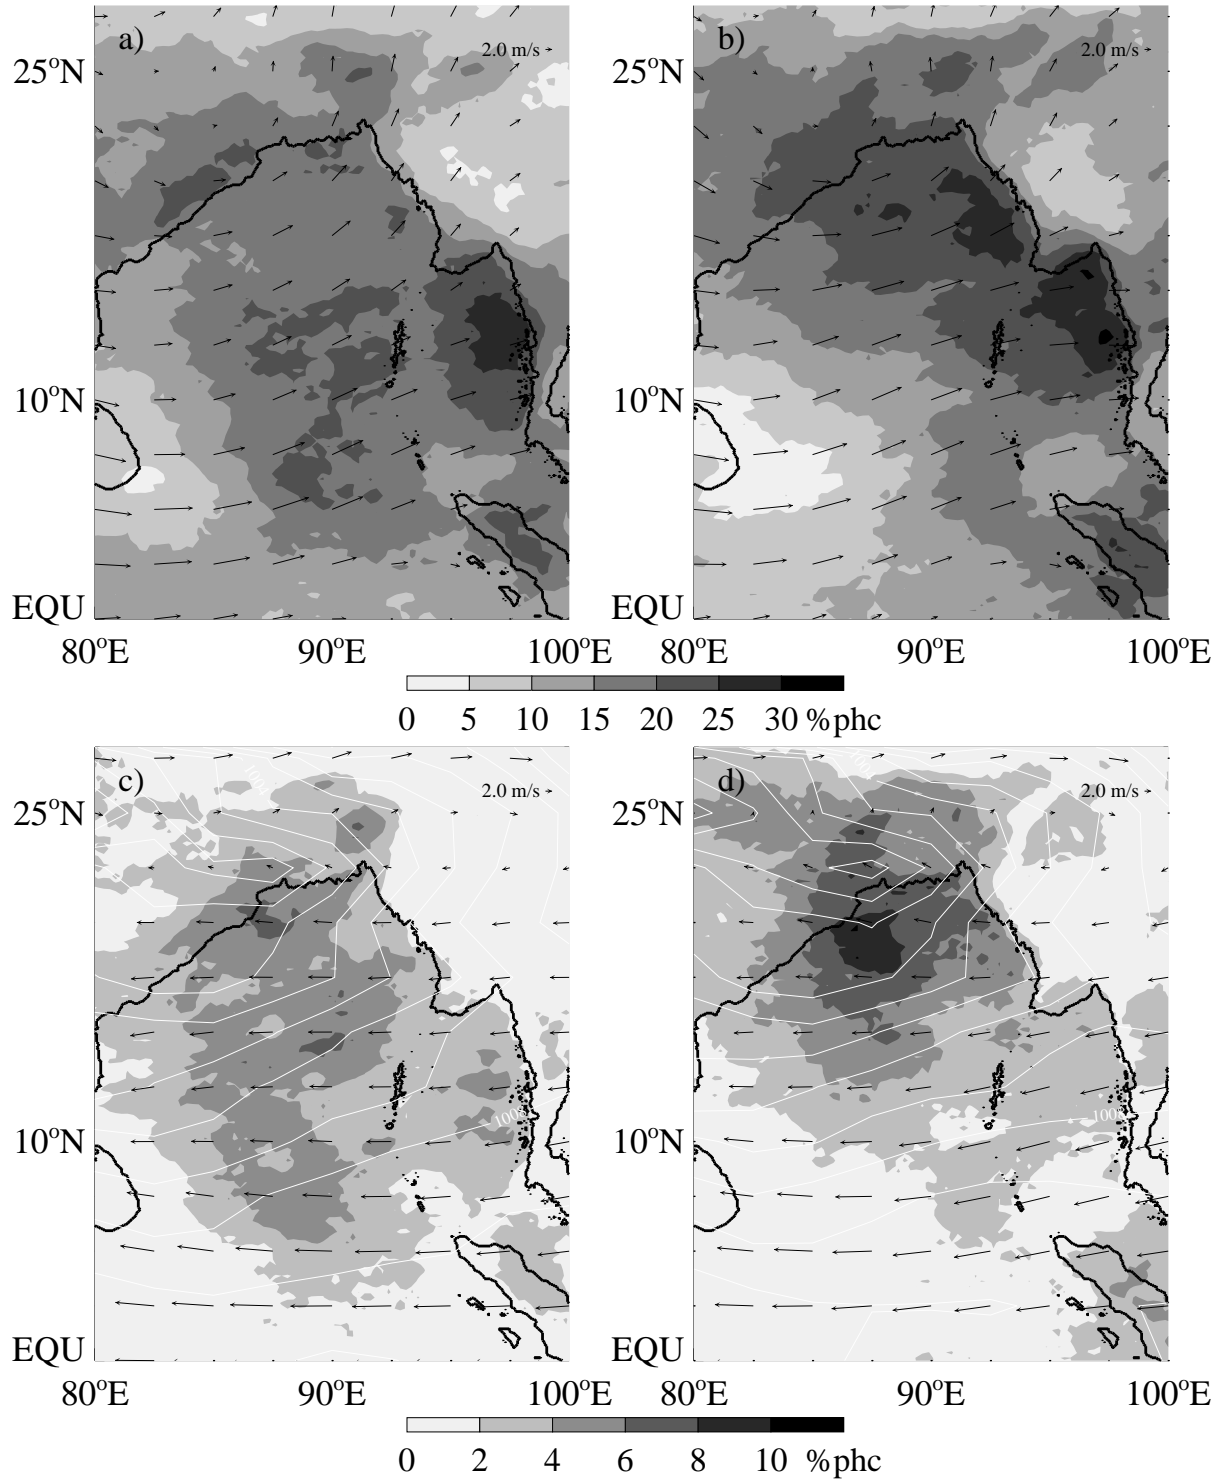

FIG. 5. Monsoonal-mean (May 1–September 30) percent high cloudiness maps for (a) 1988 PHC_{235} , (b) 1999 PHC_{235} , (c) 1988 PHC_{210} , (d) 1999 PHC_{210} . Superimposed in (a) and (b) are the NCEP Reanalysis May–September mean 850-mb winds (arrows) for the respective years. Panels (c) and (d) include the NCEP Reanalysis May–September mean 300-mb winds (arrows) and sea level pressure (white line; 1-mb contour levels). Percent High Cloud is defined as the percentage of pixels with $T_b < T_{\text{threshold}}$ of the existing images.

FIG. 6. Line shown the running 3-day-mean PHC_{235} averaged over the Bay of Bengal (10°N - 25°N , 80°E - 100°E) for 1999, while filled circles indicate the size of the individual cloud cluster elements ($T_b < 210\text{K}$) from May 1 until September 30, of 1999.

FIG. 7. Same as Fig. 6 but for 1988. Note the larger range of values for the cloud cluster sizes.

3. General Context of the 1988 and 1999 Monsoons

Figure 5 shows the monsoonal-mean (May 1 - September 30) percent high cloudiness for (a) 1988 $T_b < 235\text{K}$, (b) 1999 $T_b < 235\text{K}$, (c) 1988 $T_b < 210\text{K}$, and (d) 1999 $T_b < 210\text{K}$. The monsoonal-mean 850-mb wind field is included in panels (a) and (b), and the monsoonal-mean 300-mb wind field and the sea level pressure in panels (c) and (d). Percent high cloud (PHC) is defined as the percentage of pixels with $T_b < 235\text{K}$ (PHC_{235}) or $T_b < 210\text{K}$ (PHC_{210}) within the dataset.

Figure 5 shows that in 1999 much of the high cloudiness occurred near shore, either on the east side for PHC_{235} , or on the northwest side for PHC_{210} . In contrast, in 1988 the high cloudiness was less localized and more of it extended farther south into the Bay. Averaged over the 80°E - 100°E , 5°N - 25°N region, slightly more high cloudiness occurred in 1999 than in 1988 (16.3% vs 15.6% for PHC_{235} and 3.1% vs 2.8% for PHC_{210}).

We can compare this to the popular All-India Rainfall Index (AIRI), an average of station rain gauge data within India that is often used as an index of monsoon strength. For 1988, the AIRI was about two standard deviations above the 1871-1994 mean, while in 1999 the AIRI was slightly below the long-term mean. This implies that 1988 was a strong monsoon year and 1999 a slightly weak monsoon year. Lawrence and Webster (2001) note that the AIRI is not a good indicator of mean

convective activity in the Bay of Bengal. Fig. 5 suggests this may be because the spatial distribution of the convection varies so strongly between years that a spatially averaged value is not so meaningful. Instead, the spatial variation in the convection over water may be reflected in the spatial variation of convection over land (Bhat et al. 2001).

Fig. 5 also shows very different cloud maxima locations for PHC_{210} (panels c) and d)) than for PHC_{235} (panels a) and b)). During both years, most of the PHC_{235} is found near the eastern side of the Bay, and particularly within the Gulf of Martaban. There is a good spatial match between Fig. 5b and the 1999 TRMM mean rainfall estimate of Fig. 1. It is occurring in a region of seasonal-mean low-level onshore winds onto a coastal mountain range. In contrast, Figs. 5c and d show that the PHC_{210} cloud is more likely to be found in the northwest or west side of the Bay, with the maximum cloudiness slightly south of the mean sea level pressure minimum. This coincides with the cyclone distribution shown in Fig. 2.

4. Cloud Clusters

We find a distinct grouping of the cloud clusters by size and location, elucidated here in Section 4c. This allows us to conclude that most of the rainfall in the Bay originates from the relatively smaller cloud clus-

FIG. 8. The frequency distribution of the number of cloud clusters (expressed as the \log_{10}) for 1988 (solid line) and 1999 (dotted line) as a function of cloud cluster size.

ters. The cloud clusters of 1988 were larger than those of 1999, which implies more organized convection in 1988 than in 1999. JASMINE Star 2 was a convective exception within an otherwise relatively calm monsoon year. Lastly, a maximum cloud area occurs at 6 A.M. for all clouds irrespective of size.

a. Time Series

Figs. 6 and 7 show time series of the individual cloud clusters for 1999 and 1988, respectively, as well as a time series of the mean PHC_{235} over the Bay. For both years, the largest cloud clusters occur within the first half of the monsoon season and clearly demarcate the monsoon onset, with the cloud clusters diminishing in size in the latter half. Large cloud clusters are associated with the June 8 to 11, 1999 cyclone. The cyclone activity in both years was slightly weak (no cyclones were recorded in 1988). One-third of the cyclones shown in Fig. 2 occurred in May, suggesting that a preference for the largest cloud clusters to occur early in the monsoon season is typical.

Some of the largest cloud clusters of the entire 1999 monsoon season, and the highest spatial-mean PHC_{235} of the season, occurred during or near JASMINE Star 2, May 21 to 26, 1999. In general the larger cloud clusters occur when the mean PHC_{235} is high, but whereas the largest cloud clusters occur early on, no trend is evident in the spatial-mean PHC_{235} with time during either year. This suggests that convective activity becomes less organized as a monsoon progresses, but not less frequent.

FIG. 9. The cumulative coverage fraction of pixels with $T_b < 210K$. The dashed lines refer to the Indian Ocean domain from $20^\circ S$ - $25^\circ N$ and from 40° - $110^\circ E$, while the straight lines refer to the Bay of Bengal (5° - $25^\circ N$, 80° - $100^\circ E$). The thick lines refer to 1999 and the thin lines to 1988. The dots refer to the quartiles shown in Chen et al. (1996) Fig. 5 based on four years of GMS data.

b. Size Distribution

As seen in a comparison between Figs. 6 and 7, the cloud clusters in 1988 attain a larger size than those of 1999. This is further demonstrated in Fig. 8, showing the frequency distribution of the number of cloud clusters for each year as a function of the cloud cluster size. It is also evident that 1999 had more small cloud clusters than 1988.

Fig. 9 shows the cumulative fraction of total coverage of the Bay of Bengal as a function of cloud cluster size for 1999 (thick line) and 1988 (thin line). For further comparison, similar curves are shown for the larger Indian Ocean domain (dashed lines), and filled circles for the Japanese Geosynchronous Meteorological Satellite (GMS) domain ($80^\circ E$ - $160^\circ W$), taken from Chen et al. (1996, Fig. 5). The larger cluster elements occurring in 1988 force the entire distribution to the right. Many of these larger 1988 cloud clusters came from farther south in the Bay, where clouds were more likely to be organized into larger systems, as will be discussed further in Section 4c. We also see a tendency for more numerous large cloud clusters in the Bay of Bengal than in the entire Indian Ocean domain. The GMS values are not directly comparable,⁶ but more year-to-year variability

⁶The GMS dataset had a higher spatial resolution of 10 km.

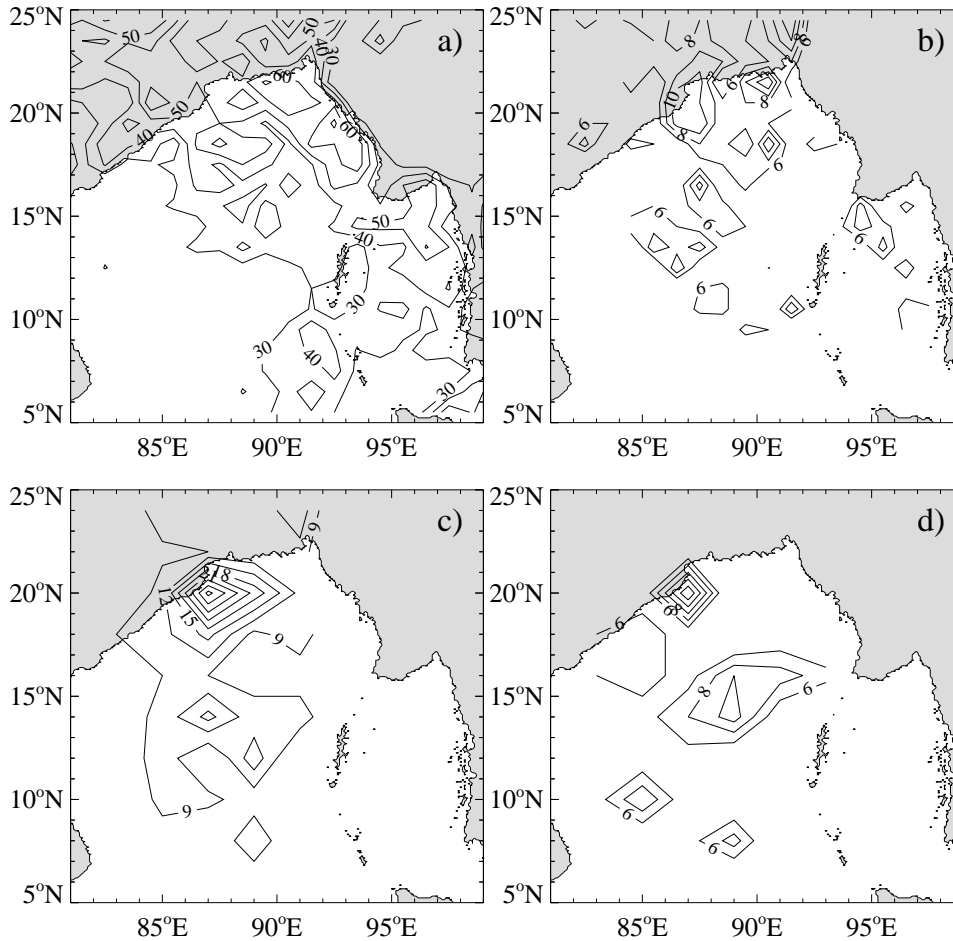

FIG. 10. Locations of the cloud clusters of both years within the a) lowest ($r < 85$ km), b) 2nd ($85 < r < 140$ km), c) 3rd ($140 < r < 210$ km) and d) top quartile ($r > 210$ km), expressed as contours of the number of clusters. Panels a) and b) are at a 1° resolution and panels c) and d) at a 2° resolution.

is seen in the two years of Indian Ocean data than was observed in the four years of GMS data, possibly a reflection of the smaller domain we examined.

c. Location

As can be seen in Fig. 10, the cloud clusters within the Bay of Bengal show a distinct spatial grouping by size. The four size groups were defined from quartiles constructed from the size distribution summed over both years, with each quartile contributing 25% to the total cloud coverage (see Fig. 9). The quartile boundaries occur at cloud cluster area sizes of 22,500, 62,500, and 136,900 km^2 . These correspond to cluster radii ($r = \sqrt{\text{area}/\pi}$) of 85, 140, and 210 km.

The smallest cloud clusters (Fig. 10a) occur either at the east side of the Bay near shore, or over land. Their distribution coincides very well with the rainfall

distribution shown in Fig. 1. As the cloud clusters increase in size, they are less likely to occur over land and more likely to occur in the middle and west side of the Bay. The largest cloud clusters over land occur over the Gangetic Plain. The largest cloud clusters ($r > 210$ km; Fig. 10d) occur primarily in only two locations: directly offshore of Pt. Palmyras at about 20°N and 87°E , and farther south in the Bay at roughly 15°N and 89°E . The northerly location is mirrored in the cyclone locations reported in Fig. 2.

Support for the overall spatial distribution exists in TRMM and Special Sensor Microwave/Imager (SSM/I) data. General TRMM data precipitation features prefer the east side of the Bay (Fig. 1) while TRMM precipitation features containing MCSs (hence more convective organization) are more equitably distributed throughout the Bay (Steve Nesbitt, pers. comm.). A population of “intense” mesoscale systems is also identified in SSM/I

FIG. 11. The diurnal cycle expressed as the percent of the daily total area for each quartile defined in Fig. 9, but for the water-only regions lying within 5° - 22° N, 80° - 98° E, defined to 1° resolution.

data in the middle of the Bay at about 17° N (Toracinta and Zipser 2001, Fig. 11).

Other similar studies conclude that large cloud systems are responsible for most of the precipitation in their locations of study (e.g., Chen and Houze 1997; Chen et al. 1996; Machado et al. 1998; Mapes and Houze 1993; Mathon and Laurent 2001). In contrast, from a comparison with TRMM data, we conclude that most of the rainfall in the Bay of Bengal comes from smaller, more numerous convective systems. Previous studies have focused on either ocean-only or land-only regions, and the explanation for the discrepancy may well reflect the impact of the coast, such as, for example, the pressure deceleration mechanism of Grossman and Durran (1984).

d. Diurnal Variability in Cloud Clusters

Figure 11 shows the diurnal cycle in the cloud coverage amount for each cloud cluster size class, expressed as the percent of the daily total cloud area. An attempt was made to isolate the diurnal behavior over the water, and the Bay of Bengal domain was restricted to water-only 1° grid boxes for this figure. The largest cloud cluster size has the most pronounced diurnal cycle, with a maximum:minimum ratio of about 10. The smaller cloud clusters have a similar phasing in their diurnal cycle, with 6 A.M. or 9 A.M. maxima and 6 P.M. or 9 P.M. minima, but their maximum:minimum ratio is much smaller,

about 2 or 3. The top quartile has an asymmetrical diurnal cycle with area coverage that increases rapidly after midnight, reaches a peak at 6 A.M., decays slowly from 6 A.M. to noon, and rapidly thereafter, reaching a minimum at 6 P.M.. This cycle in cloud area coverage will be seen again later in the time cluster life cycles.

A comparison of Fig. 11 to a similar figure derived for the western Pacific warm pool (Chen et al. 1996) reveals that the most pronounced diurnal cycle also exists for the largest cloud clusters of the tropical western Pacific warm pool, but negligible amplitudes exist for the smallest two quartiles. Most of the Bay of Bengal cloudiness occurs near shoreline, and one influence of land may be to impose a dawn maximum upon all clouds irrespective of size. The weak afternoon convection over open water found by Chen and Houze (1997) is not evident here.

5. Mean Diurnal Variability

How does land influence the cloudiness diurnal cycle over the Bay? We investigate this here through documenting the Bay of Bengal diurnal cycle and comparing it to that of the tropical western Pacific (TWP) warm pool. We chose the tropical western Pacific not only because much of it is far away from land, but also because the TWP also experiences high sea surface temperatures and is at a low latitude, and, it has a well-examined diurnal cycle. The largest difference in the diurnal cycle between the two regions is found to be nocturnal initiation times in the Bay of Bengal occurring near shore versus late-afternoon initiation times over the TWP (or land). The time of maximum cloudiness in the Bay of Bengal is slightly later than that of the TWP (but not after dawn), and the dissipation times are similar for the two regions.

We find that the convective lifecycle in the Bay of Bengal depends strongly on location. The convection occurring near land begins close to shore, with subsequent convection occurring up to ~ 300 km offshore. Farther away from land (~ 1000 km) the diurnal cycle resembles that of the open ocean. The northwest side of the Bay has the most pronounced diurnal cycle.

a. Mean 3-hourly PHC_{235} and PHC_{210}

Figures 12 and 13 show the 3-hourly diurnal cycles in PHC_{235} and PHC_{210} , respectively, for May-September of 1988 and 1999 combined. The local time stated in the panels is the local time appropriate for 90° E.

Over land the behavior of PHC_{235} and PHC_{210} is very similar, with an intense and short-lived peak in activity occurring around 6 P.M.. The maximum cold cloudiness

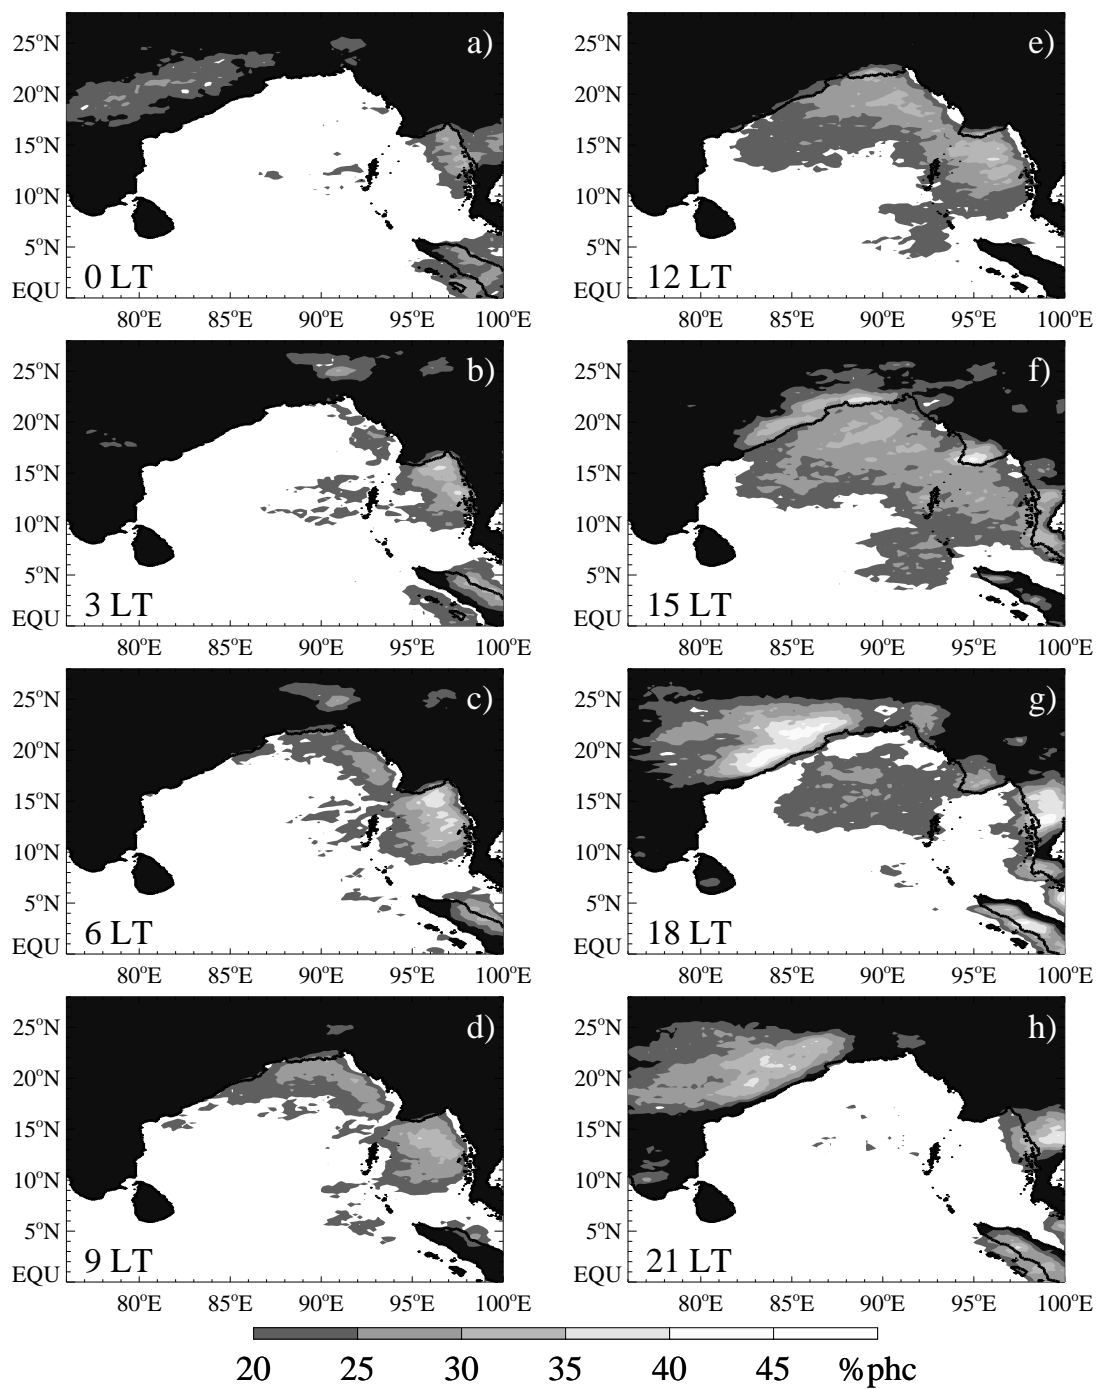

FIG. 12. The diurnal cycle in PHC₂₃₅ percent high cloudiness shown at 3-hourly time intervals. The stated local times are appropriate for 90°E. Panels a) through h) refer to local midnight, 300 LT, 600 LT, 9am, local noon, 1500 LT, 1800 LT, 2100 LT, respectively.

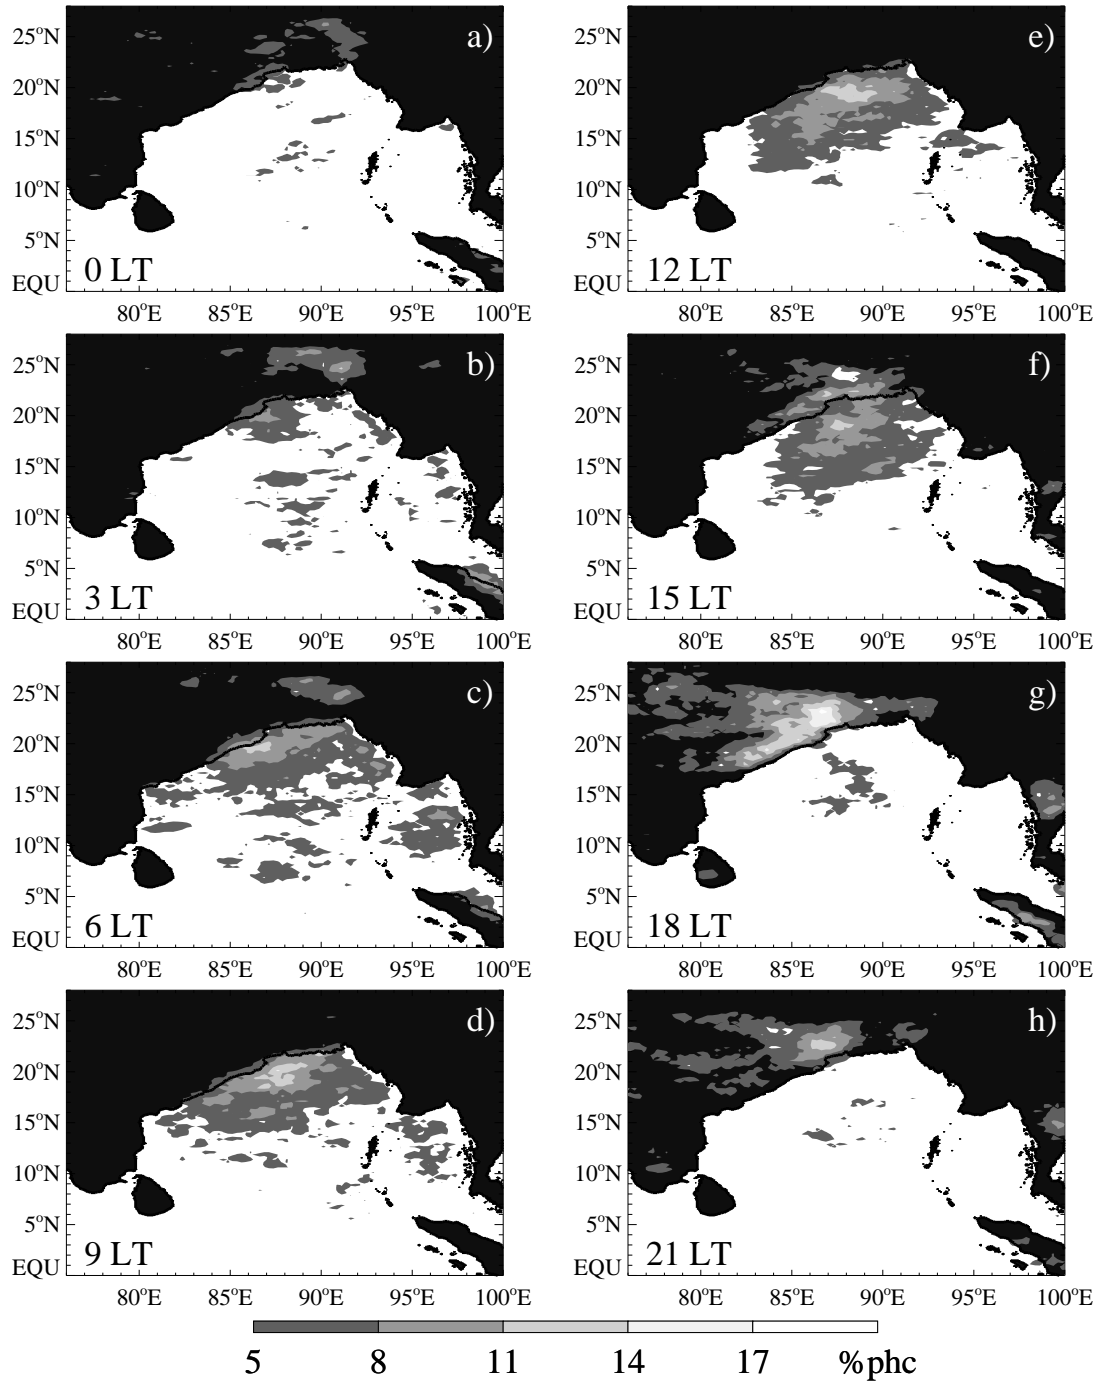

FIG. 13. Same as Fig. 12 but for PHC₂₁₀ pixels.

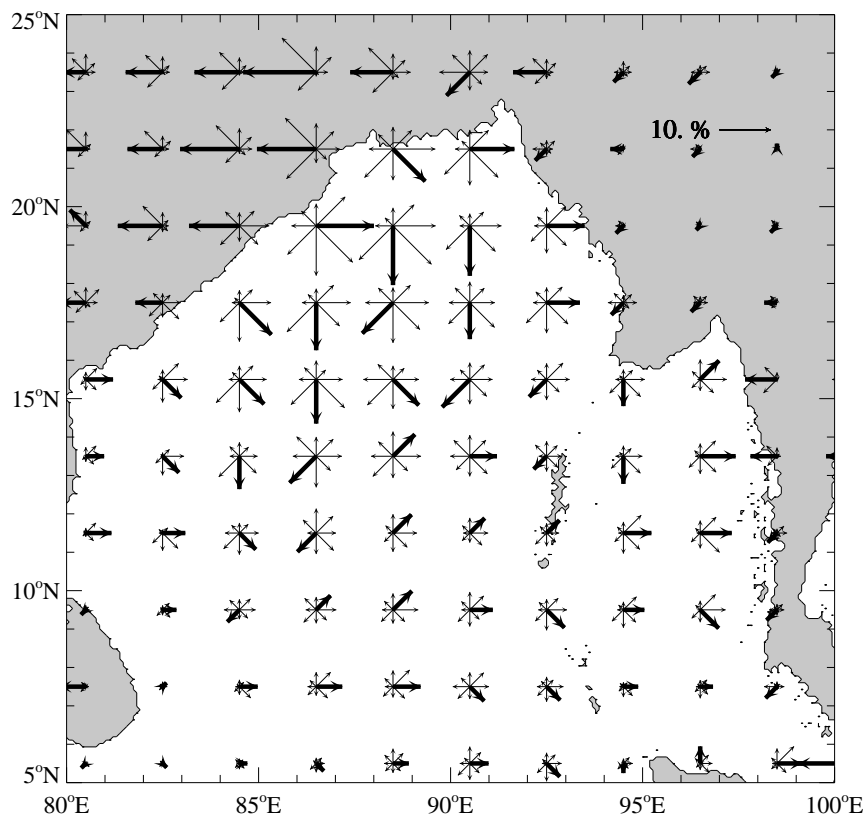

FIG. 14. Diurnal variability in PHC_{210} . The orientation and length of the vector indicates the time and the cloudiness amount, respectively. A vector pointing to the north, east, south, and west indicates 0LT, 6LT, 12LT, and 18LT respectively. The thickest vector of each cluster corresponds to the time of the maximum cloudiness amount. Each cluster represents a 1° by 1° average and is shown subsampled every 2° .

amount of the whole region occurs at this time, north-west of the Bay ($\sim 17^\circ$ – 20° N, 82° – 87° E). By 3 A.M. the land clouds are gone, aside from a peak in cloudiness occurring over Bangladesh. This coincides with the location of Cherrapunji, world record holder of the highest mean annual rainfall. Rainfall gauges also record a late-night, early-morning maximum at this site (Ohsawa et al. 2001).

Over water, the maximum PHC_{235} occurs at the east side of the Bay and the maximum PHC_{210} at the north-west side. Both PHC_{235} and PHC_{210} begin to develop in the late evening to midnight, reach a maximum area at 6 A.M., maintain a large area for 3 to 6 hours, then dissipate slowly before noon and rapidly thereafter. By 9 P.M. the Bay has a minimum in cold cloudiness, with significant PHC_{235} occurring only in the Gulf of Martaban. Over open water farther south in the Bay about 1000 km

from land (5° – 10° N, 85° – 90° E), PHC_{210} is highest from 3 A.M. to 6 A.M.. This is similar to the late-night maximum seen over the open ocean (e.g., Gray and Jacobsen 1977) and is consistent with the nighttime rainfall maximum recorded on the R/V *Ron Brown* during JASMINE Star 2.

b. Diurnal Maxima and Phasing

The local time and amount of cloud maximum is quantified for both PHC_{210} and PHC_{235} in Figs. 14 and 15. In these figures, the diurnal variability is represented as a vector every three hours, with the length of the vector indicating PHC amount and the vector direction indicating the local time. The maximum diurnal PHC is shown as a thicker vector. In this way one can infer the time of maximum convective activity, the amount, and

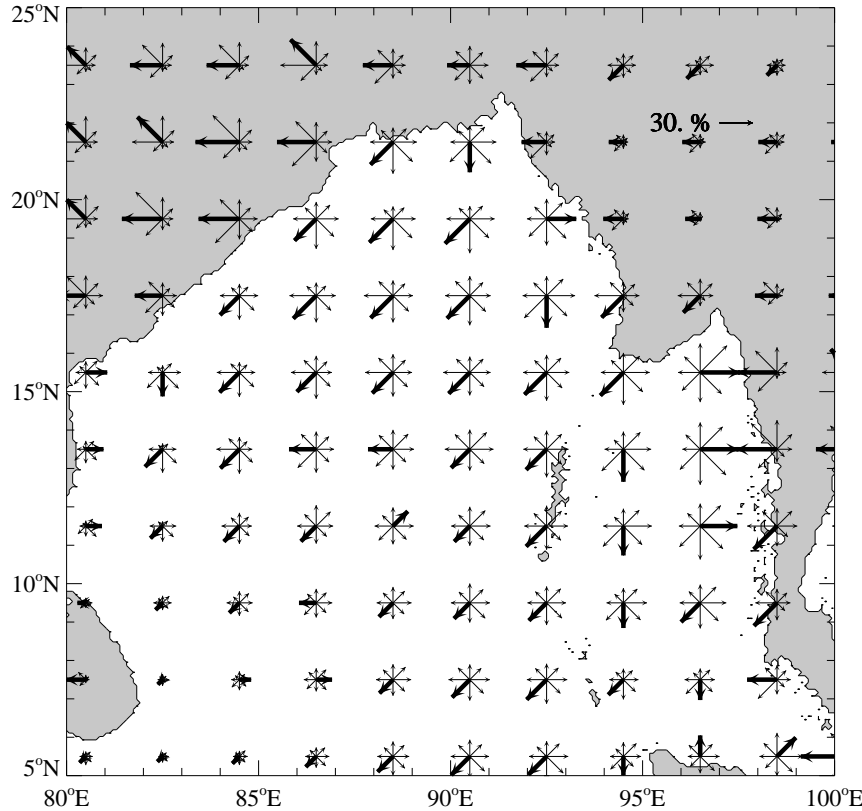

FIG. 15. Same as Fig. 14 but for PHC_{235} .

the duration from one figure⁷. From Fig. 14, we can see that most of the $T_b < 210\text{K}$ activity occurs in the northwest side of the Bay, and has a broad maximum spanning from 6 A.M. to noon (in contrast to the more short-lived neighboring land convection peaking at 18 LT). Much of the peak convective activity within the Bay occurs between 6 A.M. and 12 A.M..

Fig. 15 is similar to Fig. 14, but for PHC_{235} . Several contrasting features are apparent. One is that the diurnal cycle is more uniform over the Bay. Another is that the

time of maximum cloudiness now mostly occurs in the afternoon, with a few mostly near-shore exceptions. This figure is consistent with Fig. 3 of Ohsawa et al. (2001), yet note that the diurnal maximum of the northwest side of the Bay is different in Fig. 15 than in Fig. 14. Fig. 14 shows a 6 A.M. diurnal maximum that is consistent with rain gauge rainfall data (Ohsawa et al. 2001), whereas Fig. 15 does not accurately capture the maximum time for this location.

The land influence on the diurnal cycle over the Bay is more obvious through its impact on the strength than on the timing of the diurnal maximum. With distance away from land, the diurnal cycle becomes weaker. The effect on timing seen here is similar to that previously noted by Yang and Slingo (2001) and Ohsawa et al. (2001). They observe that in the northwest side of the Bay, convective activity farther offshore (by up to 5°) reaches its maximum later than activity close to shore⁸. In Fig. 14, this

⁷The figure is a departure from the diurnal harmonic method in which amplitude and phase of diurnal variation are derived from the first harmonic derived from 3-hourly data. Harmonic analysis has the advantage that phase information can be obtained with a higher temporal resolution than the original data. Problems with the harmonic analysis approach have been demonstrated by Ohsawa et al. (2001) for this region, however, primarily because the diurnal cycle can contain minima and maxima that are separated by only six hours. Particularly near coastlines, the first harmonic may not capture the true diurnal variation very well.

⁸Yang and Slingo (2001) as a minimum in convective activity de-

FIG. 16. Time cluster lifetime vs. maximum radius attained

would be indicated by a clockwise rotation in the thickest vector with distance offshore. We do see this in Fig. 14, more clearly in higher resolution plots not shown here. The phasing is only mostly coherent north of about 14°N for PHC_{210} .

In both Fig. 14 and Fig. 15 the phasing between the near-shore and off-shore convective maximum is most apparent at those locations with strong near-shore diurnal cycles (northwest and east sides of the Bay for PHC_{210} and PHC_{235} respectively). The phasing is clear up to about 5° or 500 km away from land, and at a distance of about 10° or 1000 km away from land the timing of the diurnal cycle no longer shows any land influence.

6. Cloud Life Cycles

This section presents the lifecycle development of the $T_b < 210\text{ K}$ time clusters. In summary, all the cloud systems attain their maximum area at 6 A.M., irrespective of size, but the larger longer-lived systems tend to begin earlier and dissipate later. The nighttime genesis times of many of the time clusters contrasts with the late-afternoon times found for the TWP. The most common cloud system propagation is to the west-southwest.

a. Spatial and Temporal Characterization

Figs. 11 to 15 lead us to expect life cycles that vary by cloud size and location. The local time and location

rived from the first harmonic of the diurnal cycle.

of the genesis, maximum cloud area, and dissipation for three time cluster groups are shown in Figs. 17 to 19. The groups were established using maximum cloud radii of 85, 140, and 210 km, similar to the quartile divisions used for Fig. 11. Clouds with maximum cloud cluster radii of less than 85 km mostly only lasted for one frame (as predicted by Machado et al. (1998)) and are not shown. Larger cloud systems tend to have longer lifetimes, as shown in Fig. 16. The top three quartiles have mean lifetimes of 19, 9, and 6 hours respectively, but there is a lot of variation.

The largest time clusters, shown in Fig. 17, tend to be over water. Many begin near the north end of the Bay and move southwestward thereafter. A more stationary population exists around Pt. Palmyras, so that a few time clusters contribute strongly to the bull's eye in cloud cluster number seen in Fig. 10d. The initiation times shown in Fig. 17 peak from 9 P.M. to 3 A.M. for the water-based clusters and at 3 P.M. for the land-based clusters (deduced from a data subsetting not shown here). A more detailed investigation shows many of the time clusters over water increase rapidly in area after midnight, attain their maximum area at 6 A.M., then decay slightly throughout the morning but rapidly after noon. Time clusters lasting more than one day survive the daytime decay, expand again the second night and usually attain their maximum area coverage on the second night, again at 6 A.M..

Fig. 18, for the next largest time cluster group, shows a similar but perhaps more localized preference for the northwest side of the Bay, both for land-based and water-based clusters. The greater localization may reflect a shorter mean lifetime that leaves less time for cloud displacement. The initiation times peak at 3 A.M. over water (later than the peak initiation time for the largest systems) and at 3 P.M. over land. The maximum areas occur at 6 A.M. over water (same as for the largest systems) and 6 P.M. over land. The most common dissipation time is at 9 A.M. or thereafter (slightly earlier than for the largest systems). Fig. 19 shows a similar life cycle for the smallest time clusters, with a slightly earlier most common dissipation time of 6 A.M. or thereafter over water. As the time clusters diminish in size, a greater proportion of them are seen over land.

The few large time clusters that occur over land (Fig. 17) deserve mention. These usually begin around 3 P.M. and, similar to the water-based clusters, attain their largest, single, contiguous cloud area at 6 A.M.. Yet, over land, the most common cloud type is small and short-lived (see Fig. 10), and occurs around 6 P.M.. For the most long-lived systems, these shorter-lived clouds can meld with the larger systems so that the maximum area of the time

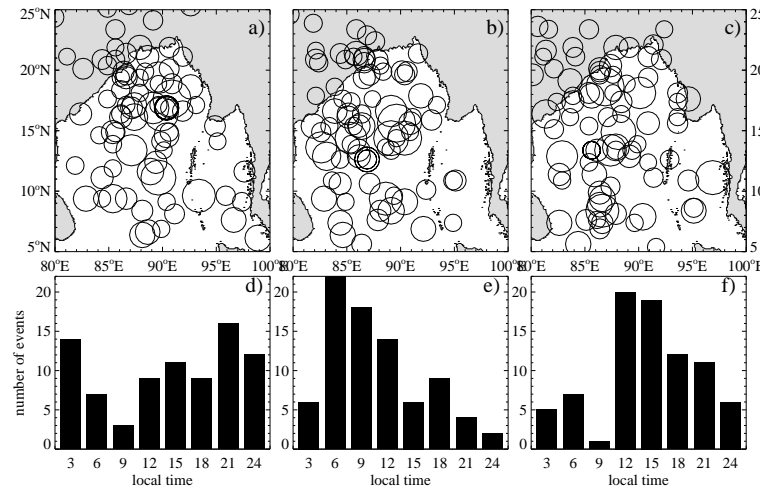

FIG. 17. Locations at the time of (a) genesis, (b) maximum areal extent, and (c) ending, for time clusters with maximum cluster radii >210 km. The local time at the beginning (d), (e) maximum areal extent, and (f) ending of the time cluster life cycle.

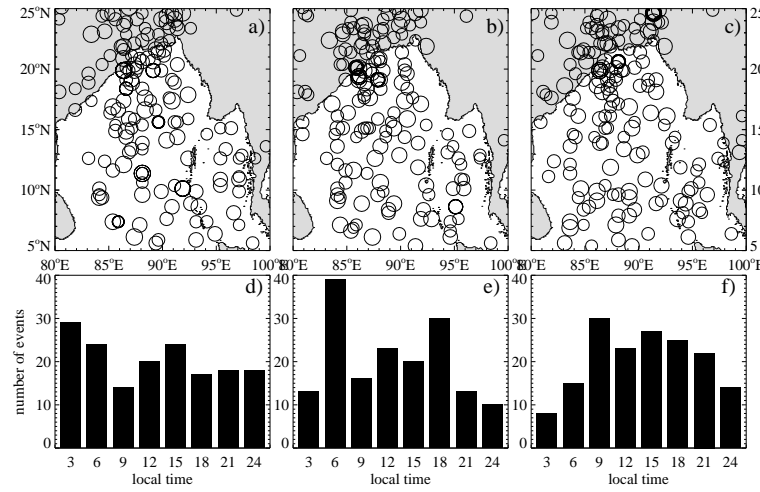

FIG. 18. Same as Fig. 17 but for time clusters with maximum cluster radii between 140-210 km.

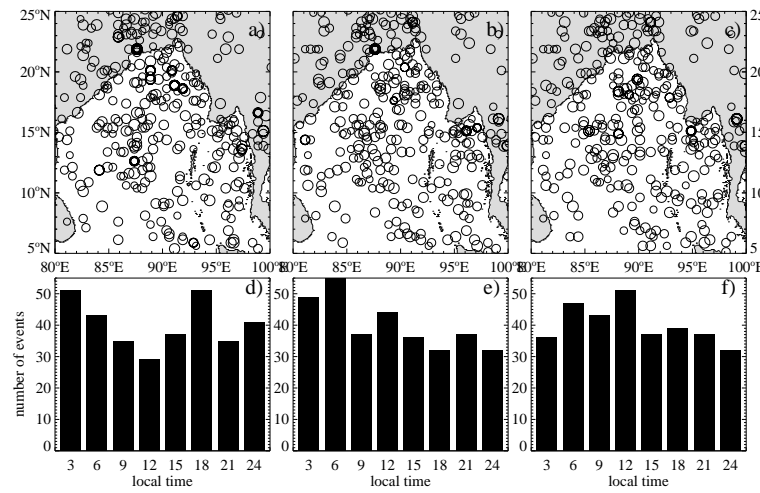

FIG. 19. Same as Fig. 17 but for time clusters with maximum cluster radii between 85-140 km.

cluster (which can contain more than one cloud cluster at any one time) can occur in the evening. An example of this is shown in Fig. 3d.

b. Comparison to Tropical Western Pacific

Chen and Houze (1997) have done a similar analysis for cloud life cycles over the western Pacific warm pool, and find an initiation time of about 3 P.M. for both small and large cloud systems. Chen and Houze (1997) attribute this to daytime boundary-layer warming. In contrast, we find a preference for nighttime 9 P.M. - 6 A.M. initiation times, particularly near land. The difference in the two initiation times is a direct reflection of the influence of the land-sea interface to the genesis process within the Bay of Bengal. In a data subsetting not shown here, systems farther south in the Bay and farther away from land were more likely to start in the late afternoon (similar to results in Chen and Houze (1997)) than those farther north.

For the other life cycle stages (maximum area and ending), both our study and Chen and Houze (1997) observe pre-dawn cloud maxima independent of location, and late-morning dissipation. This suggests cloud development and dissipation processes that are independent of the initiation process and of the particular location. Examples can include nighttime cloud-top longwave cooling, and daytime cloud shortwave absorption.

c. Cloud System Propagation

One motivation for this study was to investigate cloud movement within the Bay of Bengal. A common plotting device is to show the propagation direction averaged over all systems; in this case the mean propagation direction is southward everywhere in the Bay (not shown). However, the mean feature would hide much individual variability. A histogram of the trajectories, Fig. 20, shows cloud systems moving in most directions except north, and preferring west and southwestward movements. This reflects in part a consistent, westward offshore movement of nighttime convection in the Gulf of Martaban (discussed further in Section 7a), and cloud motions that follow the mean, upper-level winds (see Figs. 5c and d), particularly for the month of September, when the monsoon has weakened. Throughout most of the Bay during May-August, most individual motion trajectories contain a southward component.

The cyclone tracks shown in Fig. 2 almost always follow north-moving or northwestward-moving trajectories. West-northwest movement of 7-9 day activity in northeastern India and the northern Bay of Bengal is doc-

FIG. 20. Direction of propagation for all 1988 and 1999 systems whose total movement exceeded 100 km, calculated from the beginning and ending location. Results are shown for 30° bins, as measured clockwise with due north = 0°. The largest 25% of the storms (as given by their total life cycle cloud area coverage) are shown in grey.

umented by Lau and Lau (1990). In contrast, Fig. 20 shows few systems with a northward component to their propagation. Separate directions of movement for 1-2 day activity and 5-10 day activity in the Bay of Bengal contrast, for example, with the western African region, where cloud time clusters propagate in the same direction as larger-scale easterly waves (Mathon and Laurent 2001).

An example is made of the cloud systems composing the 1999 cyclone in Fig. 21. The contributing individual cloud systems generally moved to the southwest, while subsequent events would begin northwest of the previous event. In this way, the overall cyclone movement is to the northwest. The cyclone clouds attained their maximum size (and the cyclone its strongest winds) near Pt. Palmyras, emphasizing the importance of that particular region.

7. Discussion of Selected Locations

In this section three locations are used to illustrate more fully some characteristics of convection within the Bay. An in-depth examination into plausible explanations for the observations would be helped by a modeling effort that is beyond the scope of this paper; the

aim of this section is more to suggest fruitful avenues for further research. The Gulf of Martaban serves to illustrate the impact on cloud cover of monsoonal flow upon coastal mountains, the Pt. Palymras region is the site of large-scale disturbances, and lastly, a context is provided for the JASMINE Star 2 intensive observing period.

a. Gulf of Martaban

The Gulf of Martaban has a pronounced diurnal cycle in convective activity. As shown in Fig. 22, at midnight a population of primarily small, weak (cloud areas $< 22,500 \text{ km}^2$) yet relatively abundant $T_b < 210 \text{ K}$ cloud clusters is seen over water, with a sharp boundary delineating clear conditions over land. Nine hours later, the clouds have moved 200–300 km west, away from land, and have grown in size (seen in cloud cluster size distributions not shown here). By noon, the cloud population over water has become localized off of the Iriwaddy delta. These decay rapidly thereafter, followed by a pronounced 3 P.M. maximum over the Iriwaddy delta. The diurnal cycle over water is similar to that observed off the coast of N. Borneo during the winter monsoon season (Houze et al. 1981), and off the coast of Colombia (Mapes et al. 2002).

Several mechanisms may play a part in explaining the pronounced diurnal cycle observed within the Gulf of Martaban. One is that of Grossman and Durran (1984), who explain convection offshore of the Indian Ghat Mountains as a response to upstream pressure deceleration of the monsoon flow by the coastal mountains. An examination of the diurnal cycle was beyond the scope of their study, however, a thermal process could provide a diurnal cycle to the pressure deceleration that can preferentially support nocturnal convection. For example, one such process is presented in a recent modeling study of nocturnal convection offshore of Colombia (Mapes et al. 2002). This study ultimately held gravity waves emanating off of land topography responsible for the nighttime offshore convection initiation. A coastal mountain range is present near the Gulf of Martaban (see Fig. 4) and could well generate both upstream blocking, and diurnally-varying gravity waves.

In addition, the concept of a nighttime land breeze has long been used to explain nocturnal offshore convection (see Neumann 1951, and references therein). For example, Houze et al. (1981) explain their observed diurnal cycle as a convergence of a nighttime land breeze with the dominant monsoonal flow. This explanation has recently been modified by Ohsawa et al. (2001) to include consideration of shoreline curvature. Ohsawa et al. (2001) find a late night-early morning convective peak

at the N. Borneo location studied by Houze et al. (1981) even when the nighttime land breeze is in the same direction as the prevailing wind, such as occurs during summer. Ohsawa et al. (2001) attribute this to the concave coastline favoring a nighttime, low-level convergence from the concentration of land breezes, regardless of the prevailing wind. They find that late night convective activity is especially true of coastal waters with a concave coastline, and present the mouth of the Ganges River as one example. The Gulf of Martaban can serve as another example. A modeling study of the Florida peninsula, occurring at about the same latitude as the Bay of Bengal (but lacking mountains), supports the idea that coastline shape is influential in determining the timing, location, and intensity of offshore convection (Baker et al. 2001).

b. Pt. Palymras

Whereas the cloud cover on the east side of the Bay is thought to reflect the response of a monsoonal flow upon the coastal mountains, the cloud cover around Pt. Palymras is probably more linked to larger-scale circulation features. Here, the land surface is the moist low-lying Gangetic Plain. The nighttime land breeze does not converge with the prevailing monsoonal wind. A large monsoonal-mean surface low occurs (see Fig. 5). This region is a site of active transients (Lau and Lau 1990), with maxima in the 850 mb relative vorticity used to indicate tropical disturbance centers. Fig. 23 similarly shows a maximum around Pt. Palymras in the mean NCEP 850 mb relative vorticity for the two monsoon seasons combined (the individual years are similar). The connection between local disturbances and the more global circulation is demonstrated by a preferential occurrence of cyclones in the Bay of Bengal (and elsewhere) during the convective phase of the Madden-Julian Oscillation (Liebmann et al. 1994).

What is the impact upon cloud cover characteristics? The favorable conditions for convection help support large, long-lived, sometimes slow-moving systems (see Figs. 10 and 17). In contrast to the Gulf of Martaban, the spatial distribution of the cloud cover is less sensitive to the coastline (see, for example, Fig. 21). The cloud systems generally stay close to shore, with most of the cloudiness residing apparently non-preferentially either over land or over water. The direction of movement is as likely to be parallel to the coast as perpendicular to it.

The diurnal cycle is stronger than that at the Gulf of Martaban (see Fig. 14), especially near land, but both locations have 6 A.M. maxima, while the larger systems around the northwest side of the Bay have earlier initiation times (9 P.M. vs midnight) and later decay times

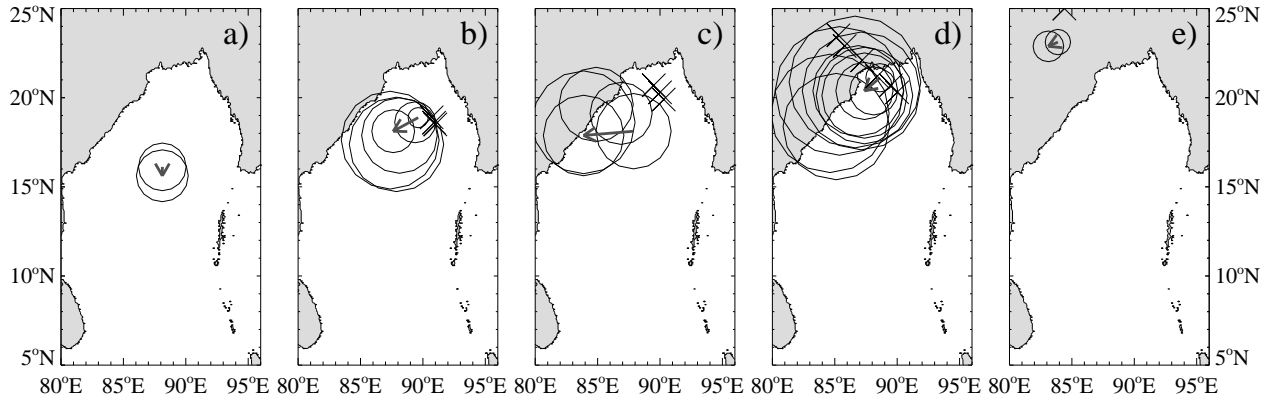

FIG. 21. Individual cloud time clusters identified within the cyclone of 8 June - 11 June, 1999. Arrows point from the first to the last cloud cluster within each sequence. Large X's indicate the cyclone position as determined by the Joint Typhoon Warning Center in Guam. Panel a) is from 6 - 9 LT 8 June, b) 21 LT 8 June - 12 LT 9 June, c) 24 LT 9 June - 12 LT June 10, d) 6 LT 9 June - 12 LT 11 June 11, e) 21 LT 11 June - 3 LT 12 June.

(afternoon vs noon) than the Gulf of Martaban systems. Again, this may reflect conditions favorable for convection occurring at time scales greater than a day for the northwest Bay. The timing of the peak convection over water becomes delayed with distance from land (Ohsawa et al. 2001; Yang and Slingo 2001), similarly to the Gulf of Martaban. This can hypothetically also be explained through gravity waves emanating from the coast, but in the case of the northwest side of the Bay, the origin of the gravity waves is land convection rather than land topography. This mechanism has not been modeled for this region, however, and at present can only be postulated.

c. JASMINE "Star 2" ($89^{\circ}\text{E}, 11^{\circ}\text{N}$, May 21-26, 1999)

As mentioned in the Introduction, during the JASMINE Star 2 time period, large, nocturnal, southward-moving disturbances were observed (Webster et al. 2002). Most of the rainfall on the R/V *Ron Brown* occurred between 2100 LT and 600 LT. Such disturbances had not been documented previously at this location. How do the JASMINE observations fit in with the convection climatology presented in this paper?

The nocturnal rainfall is consistent with the climatological diurnal variability expected for this location, as seen, for example, in Figs. 12 and 13, with an early morning maximum in the very cold clouds ($T_b < 210\text{K}$) and a late afternoon increase in slightly less cold clouds top ($T_b < 235\text{K}$). This diurnal cycle is typical of tropical oceanic convection (Chen and Houze 1997; Gray and Jacobson 1977) and implies a diminished influence of land on the diurnal cycle at this location.

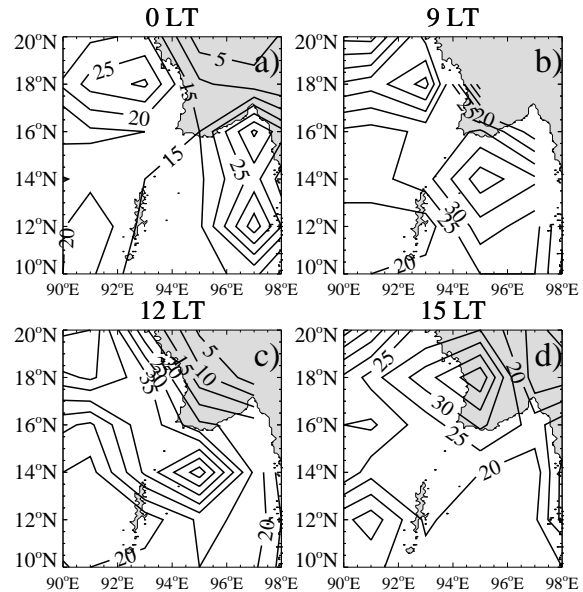

FIG. 22. Cloud cluster number at a) local midnight, b) 900 LT, c) local noon, d) 1500 LT, for both years combined. Cloud clusters have a maximum radii of 85 km.

A multi-day sequence of large, diurnally repeating, southward-moving time clusters only occurred once at this location in the two years of our cloud-tracking dataset. This would suggest that such events are unusual. In fact, both the direction of motion and the cloud cluster size are in keeping with the two-year climatology. For the southern Bay of Bengal ($85^{\circ}\text{E}-95^{\circ}\text{E}$, $5^{\circ}\text{N}-15^{\circ}\text{N}$), long-lived

FIG. 23. Combined May-September 1999 and 1988 mean 850 mb relative vorticity. Contour interval is $2 \times 10^{-6} \text{ s}^{-1}$. Derived from the NCEP Reanalysis daily-average winds at 2.5° spatial resolution.

systems of both years tended to move south. As shown in Fig. 10, a second maxima of large cloud clusters (most of them from 1988) occurs near (slightly north) of where Star 2 was held.

It is probably only their degree of organization and size that made the disturbances of Star 2 unusual. Fig. 24 shows a time-latitude plot of the brightness temperature averaged over 85°E - 90°E for May, June, and July of 1999. Diurnal, southward-propagating convective activity can be seen to occur in all three months, but the most pronounced activity occurred in May during JASMINE Star 2. Early cloud observations over the India landmass report that pre-monsoon convection in northeast India is more intense than the monsoonal convection (Ludlam 1980). The behavior during JASMINE may mirror the behavior over land, and, there may be a more explicit connection: at least one of the Star 2 events clearly originates over land (see Fig. 3d), a feature that was otherwise uncommon for such southerly time clusters. The convective intensity may also be aided by the presence of mid tropospheric dry air during the early parts of Star 2 (cite[see][Fig. 9]Webster02b), which can increase downdraft evaporation and thereby the intensity of the cold pool (Redelsperger and Lafore 1988). This would be particularly effective after a period of suppressed activity in an environment otherwise favorable to convection (Redelsperger et al. 2002).

How do the JASMINE events relate to the disturbances surveyed by Lau and Lau (1990)? They per-

formed a composite analysis of high 850 mb relative vorticity events occurring in the north end of the Bay. During Star 2, the daily-averaged NCEP 850 mb relative vorticity maxima were high, ranging between 22 to $49 \times 10^{-6} \text{ s}^{-1}$, and remained in the northwest end of the Bay. Yet, the JASMINE events does not follow the life cycle of the “typical” disturbance of Lau and Lau (1990). Their documented generally westward propagation is a net tendency, where the westward tendency associated with the advection of the mean absolute vorticity by transient fluctuations is stronger than the eastward tendency associated with the advection of vorticity fluctuations by the time-mean flow (Lau and Lau 1992). In the particular case of May 21 to 26, 1999, the dynamical balance may well differ from that of the mean picture.

8. Summary

This paper characterizes cloudiness and convection over the Bay of Bengal using 3-hourly satellite infrared data from 1988 and 1999. Percent-high-cloudiness is defined using two infrared brightness temperature thresholds, 210 K and 235 K, and the life cycles of very cold clouds ($T_b < 210 \text{ K}$) are tracked.

The two years, 1988 and 1999, have mean PHC_{235} and PHC_{210} amounts that are fairly similar but their spatial distributions are quite different. In 1988, the cold cloudiness extended farther south and was less localized. More large cloud systems occurred in 1988 than in 1999 partly because the more southern cloud systems were more likely to be large. The different spatial and size distributions of the cloud systems over water coincide with higher rainfall amounts over mainland India in 1988 than in 1999. Both years had most of their large systems occur in the first half of the monsoon.

The northwest side of the Bay is a documented site for much convective activity with significant impacts on mainland Indian weather, and this is where the maximum PHC_{210} occurs. Here the cloud systems over water and sometimes over land are large and long-lived. The individual cloud systems often contain a southward component to their motion despite being embedded within primarily northwest-moving larger-scale activity. The region around Pt. Palmyras is notable for its very large cloud clusters. Their diurnal cycle amplitude is pronounced, with a maximum:minimum cloud area ratio of about 10:1, and helps explain why the strongest diurnal cycle of the entire Bay occurs here. Cloud tops with $T_b < 210 \text{ K}$ show 6 A.M. to noon maxima, and convection initiation times are earlier and dissipation times later compared to other parts of the Bay. The phasing of convection discussed in Yang and Slingo (2001) and Oh-

FIG. 24. Time-latitude plot of the infrared brightness temperature averaged over 85°E-90°E for May through July of 1999. Dark line shows the position of the R/V *Ron Brown* throughout JASMINE. Plot courtesy of Dr. David Lawrence.

sawa et al. (2001), where convection attains its maxima at a later hour farther away from land, is also documented here.

The east side of the Bay has most of the rainfall, indeed, a maximum in global rainfall in summer. Here the PHC_{235} is a maximum, while the cloud systems ($T_b < 210$ K) tend to be small and short-lived, but relatively frequent. The cloud systems possess a regular diurnal cycle, with convection beginning offshore around 9 P.M. to midnight, later convection occurring farther offshore and attaining a larger size, and then decaying rapidly around noon. Most of the systems occur only in one 3-hourly image, so that the offshore propagation mostly consists of dissipating near-shore systems and initiating farther offshore systems. The phasing in PHC_{235} is most pronounced in the Gulf of Martaban where the diurnal cycle is strongest. At the east side of the Bay, the prevailing monsoonal flow is onshore onto coastal mountains. Responses such as the upstream blocking by pressure deceleration mechanism of (Grossman and Durran 1984), and/or gravity waves emanating off of the land topography (Mapes et al. 2002) may well be active and could explain the observed behavior.

At the southerly location of JASMINE Star 2 (89°E, 11°N), the multi-day sequence of disturbances on May 21-26, 1999 was unusual because such a sequence only occurred once in the two years of data examined. In other respects, the storms were consistent with climatology, with rainfall occurring at night, a southward propagation, and large cloud cover.

Previous studies have similarly tracked clouds for land-only or ocean-only regions of the globe (e.g., Chen and Houze 1997; Chen et al. 1996; Machado et al. 1998; Mapes and Houze 1993; Mathon and Laurent 2001). A common result is that a relatively small number of the cloud clusters generates most of the total areal cloud cov-

erage. From this observation, the conclusion is often drawn that most of the rainfall comes from a few large systems. While this may be true for other regions, over the Bay of Bengal most of the rainfall (as determined using TRMM data) comes from the smaller systems. Similarly, we find cloud motions that differ, rather than agree with, larger-scale movements. The unique conclusions for the Bay of Bengal domain reflect the complexity of a region that contains both land and water.

We compared the results for the Bay of Bengal with those of the tropical western Pacific open ocean (Chen and Houze 1997). The most significant difference occurs in the initiation times of convection, with afternoon initiation times occurring over the tropical open ocean (and land) versus nocturnal initiation times over the Bay. Another difference is that a dawn maximum exists for all cloud clusters over the Bay regardless of size, whereas the diurnal amplitude is negligible for the smaller clusters over the tropical western Pacific. Both differences demonstrate the strong influence of land on convection occurring over the water of the Bay. A land influence is clearly evident in convection occurring roughly 500 km away from land; farther away (~ 1000 km), the diurnal cycle is more subdued and more typical of the open ocean.

This study has raised many questions. The differences between the two years in the cold cloudiness location and size distribution, means that conclusions about what is typical for the region should be made cautiously, and should encourage further study for the region. A breakdown into active and break phases would be interesting. Further investigation of the diurnal cycle using data with higher temporal resolution would be interesting as would modeling studies of the land-sea dynamic at particular locations. The disturbances of May 21 to 26, 1999 deserve further study as well, towards understanding why

they were the most organized multi-day convection experienced at that location in the two years examined.

Acknowledgments. Dr. Brian Mapes is gratefully acknowledged for the use of his cloud-clustering software and overall encouragement. Many thanks to Dr. David Lawrence for piquing initial curiosity, as well as for Fig. 24 and reading in and interpolating the original INSAT data to the Meteosat-5 grid. This research was motivated by the author's participation in JASMINE and stimulating conversations occurring throughout the experiment with scientists and R/V *Ron Brown* crew alike are much appreciated. I thank John Bates, Chris Fairall, Brian Mapes, and two anonymous reviewers for useful comments on an earlier version of this manuscript. Steve Nesbitt provided helpful insight into the TRMM view of convection.

The work was begun while the author was at the Program of Atmospheric and Oceanic Sciences (PAOS), University of Colorado-Boulder. Support received then under NSF ATM-9819618 as well as subsequent use of PAOS computers is gratefully acknowledged. This work was completed while the author held a National Research Council Research Associateship Award at NOAA/ETL.

The Meteosat-5 data were provided by EUMETSAT, and the INSAT data by the NCAR Data Archive. The TRMM Level 3 data for Fig. 1 were processed and provided by the National Aeronautics and Space Administration and the National Space Development Agency of Japan and made available through its Web site <http://www.eorc.nasda.go.jp/TRMM>. NCEP Reanalysis data were provided by the NOAA-CIRES Climate Diagnostics Center, Boulder, Colorado, from its Web site at <http://www.cdc.noaa.gov>. Cyclone track data were provided by the Joint Typhoon Warning Center through its Web site <http://www.npmoc.navy.mil/jtwc.html>. The AIRI data were provided by <http://grads.iges.org/india/allindia.html>. The elevation data for Fig. 4 were provided by the US Geological Survey's EROS Data Center through <http://edcdaac.usgs.gov/gtopo30>. This paper was generated using L^AT_EX macros provided by Prof. Steve Sherwood through his website.
